## HMC

# The Basic HMC Scheme

**Hamiltonian dynamics** (from mechanics) is used in **combination with Metropolis sampling** to construct a MCMC method.

**The motivation** for HMC is to sample the state space more efficiently, so that larger movements from the current state could be made in one step than what is possible in Metropolis-Hastings (M-H) sampling. This comes at the price of increased computation per time step. Despite this, HMC typically samples states much faster than M-H.

When reading this,

1. first have a look at this [site](#).
2. Refer to it when reading.
3. After having stumbled this through, (I suggest you) play around with the graphical models on the site.

# The Basic HMC Scheme

**Hamiltonian function**  $H(q, p)$  is determined in terms of the probability distribution we want to sample from.

The “**position**” variables  $q$  are the ones we are interested in.

The “**momentum**” variables  $p$  are auxiliary that we need in order to move within the distribution and so to do the sampling. These momentum ( $p$ ) – or velocity ( $v = p/m$ ) – variables provide the more efficient sampling.

Simple updates of these variables alternate with Metropolis updates.

**Gain:** Proposed states can be distant from the current states and still have a high probability of acceptance.

# Hamiltonian Dynamics

**Hamiltonian (function)** gives the total - here constant - energy of a dynamical system.

$$H(q, p) = U(q) + K(p) = E_{tot},$$

where  $U(q)$  is the potential energy and  $K(p)$  is the kinetic energy.

The dynamical system is completely described when we know how  $q$  and  $p$  change over time  $t$ . This is stated by equations of motion, here **Hamilton's equations**

$$\frac{dq_i}{dt} = \frac{\partial H}{\partial p_i}, \quad i = 1, \dots, d ; (d \text{ is dimension})$$

$$\frac{dp_i}{dt} = -\frac{\partial H}{\partial q_i}.$$

# Hamiltonian Dynamics

Combining vectors  $q$  and  $p$  into the vector  $z = (q, p)$  we get

$$\frac{dz}{dt} = J \nabla H(z),$$

where the gradient  $\nabla H = [\nabla H]_k = \partial H / \partial z_k$ , and

$$J = \begin{bmatrix} 0_{d \times d} & I_{d \times d} \\ -I_{d \times d} & 0_{d \times d} \end{bmatrix}.$$

# Hamiltonian Dynamics

## Potential and Kinetic Energy

In  $d$  dimensions, the kinetic energy is

$$K(p) = \frac{p^T M^{-1} p}{2}.$$

$M$  is a symmetric, positive-definite mass matrix. It is often diagonal and a scalar multiple of the identity matrix; this latter part means that all “particles” have the same mass  $m$ .

**Note** that  $p = Mv$ , where  $v = \dot{q}$ , so

$$K(v) = \frac{v^T M v}{2}.$$

# Hamiltonian Dynamics

This form of  $K(p)$  corresponds to  $-\log(p_P(p)) + \text{Const.}$  Here,  $p_P(p) = N(0, \Sigma = M)$  (zero-mean Gaussian with covariance matrix  $M$ ).

$$p_P(p) = \frac{1}{Z} \exp\left(\frac{-K(p)}{T}\right) = \frac{1}{Z} \exp\left(-\frac{p^T M^{-1} p}{2}\right). \quad (T = 1.)$$

With these forms, Hamilton's equations become

$$\frac{dq_i}{dt} = [M^{-1}p]_i, \quad (\text{Velocity.})$$

$$\frac{dp_i}{dt} = -\frac{\partial U}{\partial q_i}. \quad (\text{Force.})$$

# Hamiltonian Dynamics

**Example:** One-dimensional harmonic oscillator

$$H(q, p) = U(q) + K(p), \quad U(q) = \frac{q^2}{2}, K(p) = \frac{p^2}{2m} = \frac{p^2}{2}.$$

Here, we choose  $m = 1$ .

So, distributions for both  $q$  and  $p$  are  $N(0, 1)$ .

Here, Boltzmann factor “transforms” potentials to distributions.

The dynamics:

$$\frac{dq_i}{dt} = p, \quad \frac{dp_i}{dt} = -q.$$

(Hamilton's equations)

Solution ( $a$  and  $r$  are constants determined by initial conditions):

$$q(t) = r \cos(a + t), \quad p(t) = -r \sin(a + t)$$

# Hamiltonian Dynamics

## Properties of Hamiltonian dynamics

### **Reversibility** (for deterministic dynamics – no stochastics)

The **mapping** from the state at time  $t$ ,  $(q(t), p(t))$ , to the state at time  $t + s$ ,  $(q(t + s), p(t + s))$ , is **one-to-one** and so has an inverse, which is obtained by negating the time derivatives in Hamilton's equations.

### **Conservation of the Hamiltonian** (= Constant Energy)

The dynamics keeps the Hamiltonian invariant.

$$\frac{dH}{dt} = \sum_{i=1}^d \left[ \frac{\partial H}{\partial q_i} \frac{dq_i}{dt} + \frac{\partial H}{\partial p_i} \frac{dp_i}{dt} \right] = \sum_{i=1}^d \left[ \frac{\partial H}{\partial q_i} \frac{\partial H}{\partial p_i} - \frac{\partial H}{\partial p_i} \frac{\partial H}{\partial q_i} \right] = 0$$

$$\frac{dH}{dt} = 0: H \text{ is a constant of motion.}$$

# Hamiltonian Dynamics

## Volume Preservation

Any **phase-space volume** evolving in time may change its shape but the volume does not change

$$\begin{aligned}\nabla \cdot \left( \frac{d\mathbf{q}}{dt}, \frac{d\mathbf{p}}{dt} \right) &= \sum_{i=1}^d \left[ \frac{\partial}{\partial q_i} \frac{dq_i}{dt} + \frac{\partial}{\partial p_i} \frac{dp_i}{dt} \right] = \sum_{i=1}^d \left[ \frac{\partial}{\partial q_i} \frac{\partial H}{\partial p_i} - \frac{\partial}{\partial p_i} \frac{\partial H}{\partial q_i} \right] = \\ &= \sum_{i=1}^d \left[ \frac{\partial^2 H}{\partial q_i \partial p_i} - \frac{\partial^2 H}{\partial p_i \partial q_i} \right] = 0.\end{aligned}$$

(A vector field with zero divergence preserves volume.)

In the present context this means that **probability measure** is invariant in time. (My wording, so subject to misinterpretations ☺)

# Hamiltonian Dynamics

## Symplecticity

The **volume preservation** is the most important consequence of this more universal property. Hamiltonian dynamics is symplectic. In dynamics symplecticity and volume preservation are often treated as synonyms. Symplecticity can be defined via the Jacobian of the transformation defining the propagation in time (dynamics).

In Hamiltonian dynamics the **symplectic form** is defined as  $\omega = dq \wedge dp$ . Hamiltonian flow keeps  $\int_S \omega$  invariant. (See e.g. **differentiable manifolds**, if you are interested.)

( $\wedge$  is the exterior (vector) product ( $\times$ ).)

# Hamiltonian Dynamics

## Discretization of Hamilton's Equations

### *Euler's Method*

$$p_i(t + \varepsilon) = p_i(t) + \varepsilon \frac{dp_i}{dt}(t) = p_i(t) - \varepsilon \frac{\partial U}{\partial q_i}(q(t)),$$

$$q_i(t + \varepsilon) = q_i(t) + \varepsilon \frac{dq_i}{dt}(t) = q_i(t) + \varepsilon \frac{\partial K}{\partial p_i}(p(t))$$

$$\text{We use } K(p) = \sum_{i=1}^d \frac{p_i^2}{2m_i} \Rightarrow q_i(t + \varepsilon) = q_i(t) + \varepsilon \frac{p_i(t)}{m_i}.$$

( $\varepsilon$  is the step size)

The following examples of numerical integration is for the 1-D harmonic oscillator  $\rightarrow$

# Hamiltonian Dynamics

## Discretization of Hamilton's Equations

### *Euler's Method*

(a) Euler's Method, stepsize 0.3

Integrating in time using Euler involves **numerical error**;  
try to minimise it →

# Hamiltonian Dynamics

*A Modified Euler's Method*

$$p_i(t + \varepsilon) = p_i(t) - \varepsilon \frac{\partial U}{\partial q_i}(q(t)),$$

$$q_i(t + \varepsilon) = q_i(t) + \varepsilon \frac{p_i(t + \varepsilon)}{m_i}. \quad \leftarrow \text{Here's the difference.}$$

The computed trajectory deviates less from the exact trajectory.

# Hamiltonian Dynamics

## *A Modified Euler's Method*

(b) Modified Euler's Method, stepsize 0.3

We can do still better →

# Hamiltonian Dynamics

## *The Leapfrog Method*

Propagate  $p_i$  in half steps.

$$p_i(t + \varepsilon/2) = p_i(t) - (\varepsilon/2) \frac{\partial U}{\partial q_i}(q(t)),$$

$$q_i(t + \varepsilon) = q_i(t) + \varepsilon \frac{p_i(t + \varepsilon/2)}{m_i}.$$

$$p_i(t + \varepsilon) = p_i(t + \varepsilon/2) - (\varepsilon/2) \frac{\partial U}{\partial q_i}(q(t + \varepsilon)).$$

# Hamiltonian Dynamics

## *The Leapfrog Method*

Even with increased time step the computation is stable.

(c) Leapfrog Method, stepsize 0.3

(d) Leapfrog Method, stepsize 1.2

# MCMC from Hamiltonian Dynamics

**The requirement:** Translate the **density function** for the distribution to be sampled from to a **potential energy function** and introduce momentum variables to go with the original variables of interest, now seen as position variables.

**The task:** Simulate a Markov chain in which each iteration resamples the momentum and then performs a **Metropolis update with a proposal found by using Hamiltonian dynamics**.

How do we map the probability distribution to a potential energy function?

# MCMC from Hamiltonian Dynamics

## Probability and the Hamiltonian: Canonical Distributions

From statistical physics we know that in a canonical system (temperature and volume are constant) **the probability density function for the state  $x$** , whose energy is  $E(x)$ , is the **canonical distribution (Gibbs ensemble)**. The probability

$$p_X(x) = \frac{1}{Z} \exp\left(\frac{-E(x)}{kT}\right)$$

Here,  $T$  is the temperature and  $k$  is the Boltzmann constant, which we just set to 1, since absolute energy values are of no consequence in what we do.

$$\Rightarrow p_X(x) = \frac{1}{Z} \exp\left(\frac{-E(x)}{T}\right)$$

# MCMC from Hamiltonian Dynamics

$Z$  is the **partition function**. It is the sum over *all* states in the system. It corresponds to the normalisation constant in the distributions we encounter in statistics/stochastics. Typically incalculable.

In our liberal spirit we also set  $T = 1$  and write  $E(x) = -\log P(x) - \log Z$  and choose for  $Z$  a convenient value.

Since the Hamiltonian  $H(q, p) = U(q) + K(p)$  is an energy function for the *joint state* of position  $q$  and momentum  $p$ , it defines the *joint distribution*

$$p_{q,p}(q, p) = \frac{1}{Z} \exp\left(\frac{-U(q)}{T}\right) \exp\left(\frac{-K(p)}{T}\right)$$

**$q$  represent the variables of interest and  $p$  provide the dynamics.**

$H(q, p) = E_{\text{total}} = \text{const.} \Rightarrow p_{q,p}(q, p) = \text{const.}$  when computation is exact.

# MCMC from Hamiltonian Dynamics

In *Bayesian statistics*, the distribution of interest is the posterior distribution for the model. **The posterior distribution** can be expressed as a canonical distribution ( $T = 1$ ) using a potential energy function defined as:

$$U(q) = -\log[\pi(q)L(q|D)],$$

where  $\pi(q)$  is the prior density and  $L(q|D)$  is the likelihood function given data  $D$ . ( $\log = \ln$ .)

So, to **construct the potential function** to go with the distribution, use  $\pi(q)L(q|D) = \exp[-U(q)]$ .

# MCMC from Hamiltonian Dynamics

[Betancourt](#) writes the (joint) canonical density as  $\pi(q, p) = e^{-H(q, p)}$ .

$$\Leftrightarrow H(q, p) = -\log \pi(q, p) = -\log[\pi(p|q)\pi(q)].$$

Accordingly, the decomposition of the Hamiltonian and the joint density correspond as

$$\begin{aligned} H(q, p) &= -\log[\pi(p|q)] - \log[\pi(q)] \\ &\equiv K(q, p) + V(q). \end{aligned}$$

[Notice that there's a (notational) difference here compared to Hamiltonian on the previous slide:  $V(q) = \pi(q)$  instead of  $V(q) = \pi(q)L(q|D)$ ; “target distribution” instead of “posterior distribution”; these are the same for us (no data here) for all practical purposes.]

# MCMC from Hamiltonian Dynamics

**Note** that since only the gradient  $\nabla V(\mathbf{q})$  is used in HMC, possible prefactors are of no concern. This is the reason for the sloppy definitions of the distributions in this context, which, of course, nobody cares to mention.

For example, take the target distribution  $\pi(q) = Ae^{-Bq^2}$ . We can write this as  $\pi(q) = \exp[-Bq^2 + \ln A]$ .

Then  $V(q) = -\ln \pi(q) = Bq^2 - \ln A$

$$\Rightarrow \frac{dV(q)}{dq} = 2Bq.$$

In other words, the prefactor  $A$  does not show in  $\nabla V(\mathbf{q})$  and so has no effect on the HMC implementation.

In HMC, the potential can be thus used in the minimal form  $V(q) = Bq^2$ .

In general, for any  $\pi(q) = Cf(q)$ :

$$\Rightarrow V(q) = -\ln \pi(q) = -\ln[f(q)] - \ln C \Rightarrow \frac{dV(q)}{dq} = \frac{-df(q)/dq}{f(q)}$$

and the minimal form for HMC is  $V(q) = -\ln[f(q)]$ .

# MCMC from Hamiltonian Dynamics

## The Hamiltonian Monte Carlo Algorithm

HMC can be used to **sample only from continuous distributions** on  $\mathbb{R}^d$  for which

- the density function can be evaluated (up to an unknown normalising constant)
- the partial derivative of the density function (or the gradient of  $U(q)$ ) can be computed: the derivatives must exist except for on a set of points with probability zero, where some arbitrary value can be returned

HMC samples from the canonical distribution  $p_{q,p}(q, p)$ .

$q$  has the distribution of interest, as specified by  $U(q)$ .

The distribution of  $p$  can be chosen freely via  $K(p)$ . **Common practise is to use quadratic  $K(p)$ ; consequently  $p$  has a zero-mean multivariate Gaussian distribution.**

# MCMC from Hamiltonian Dynamics

$p_i$  defined as independent with component  $i$  having **variance**  $m_i$  (and setting  $T = 1$ ):

$$K(p) = \sum_{i=1}^d \frac{p_i^2}{2m_i}$$

# MCMC from Hamiltonian Dynamics

## The Two Steps of the HMC Algorithm

### *The First Step*

Draw new values for  $p_i$ , independently of the current values of  $q_i$ . For  $K(p) = \sum_{i=1}^d \frac{p_i^2}{2m_i}$  the  $d$  variables  $p_i \sim N(0, \sigma_i^2)$ . This step leaves  $p_{q,p}(q, p)$  invariant.

*The Second Step*  $\longrightarrow$

# MCMC from Hamiltonian Dynamics

## *The Second Step*

Propose a new state by performing a Metropolis update with Hamiltonian dynamics:

Start with the current state  $(q, p)$ .

Simulate Hamiltonian dynamics for  $L$  steps using the leapfrog method (or some other reversible volume-preserving method) with a step size  $\varepsilon$ . (When  $L = 1$ , HMC is also called L(angevin)MC.)

At the end of  $L$  steps, negate  $p_i$  ( $p_i \rightarrow -p_i$ ).

Now you have **the proposed state**  $(q^*, p^*)$ .

**Accept** this proposed state (as the next state of the Markov chain) **with probability** (Metropolis) Boltzmann

$$P = \min[1, \exp(-H(q^*, p^*) + H(p, q))] \leftarrow \exp(-\Delta E)$$
$$= \min[1, \exp(-U(q^*) + U(q) - K(p^*) + K(p))].$$

# MCMC from Hamiltonian Dynamics

If the proposed state is rejected, the next state is the current state. Be sure to count the occurrences of these states also, when computing expectations etc.

The negation of the momentum is done to ensure that the Metropolis proposal is symmetric (Neal).

In fact, there is a more fundamental reason to momentum reversal (Betancourt): If only states going forward can be proposed, i.e.  $p^* > p$ , the Metropolis-Hastings acceptance probability becomes ill-posed (see Betancourt p. 39).

(Hmm... but  $K(p) \propto p^2$ , so “cut the smalltalk”, as Bogie would say.)

Return to *The First Step*.

# MCMC from Hamiltonian Dynamics

Viewing HMC as sampling from the joint distribution of  $q$  and  $p$ , the Metropolis step using a proposal found by Hamiltonian dynamics – i.e. the second step - leaves the probability density for  $(q, p)$  unchanged; in fact *almost* unchanged due to truncation in the Euler's method and finite numerical precision. (Why use Euler? Use leapfrog at every step.)

**Movement** to  $(q, p)$  points **with a different probability density** is accomplished only by the first step, the replacement of  $p$  by a new value. This replacement can change the probability density for  $(q, p)$  by a large amount.

# MCMC from Hamiltonian Dynamics

To rephrase, a value for  $q$  with a very different probability density and, equivalently, a very different potential energy  $U(q)$  can be produced by Hamiltonian dynamics. Still, resampling of  $p$  is necessary for obtaining the proper distribution for  $q$ , since without resampling the Hamiltonian  $H(q, p) = U(q) + K(p)$  would be (nearly) constant and  $U(q)$  could never exceed the initial value of  $H(q, p)$ .

## First Step:

Random lift from the target parameter space onto phase space.

## Second Step:

Deterministic Hamiltonian trajectory through phase space and a projection down to the target parameter space.

# MCMC from Hamiltonian Dynamics

FIG 22. (a) Each Hamiltonian Markov transition lifts the initial state onto a random level set of the Hamiltonian, which can then be explored with a Hamiltonian trajectory before projecting back down to the target parameter space. (b) If we consider the projection and random lift steps as a single momentum resampling step, then the Hamiltonian Markov chain alternates between deterministic trajectories along these level sets (dark red) and a random walk across the level sets (light red).

Note: Energy level trajectories of this form are for the harmonic oscillator (see page 8).

# MCMC from Hamiltonian Dynamics

## Proof of the Invariance of the Canonical Distribution

Mentally partition the  $(q, p)$  space into regions  $A_k$ , each of the same small volume  $V$ . Define  $O$  as the operation of  $L$  leapfrog steps plus a negation of the momenta such that  $O: A_k \rightarrow B_k$ . ( $B_k$  is the image of  $A_k$ .)

Leapfrog steps are reversible, so  $B_k$  also partition the  $(q, p)$  space. Since leapfrog steps and negation preserve volume, each  $B_k$  has volume  $V$ .

*Detailed balance* holds if  $\forall i, j, P(A_i)T(B_j|A_i) = P(B_j)T(A_i|B_j)$ .

Here,  $P$  is probability under the canonical distribution, and  $T(X|Y)$  is the conditional probability of proposing and then accepting a move to region  $X$  if the current state is in region  $Y$ .

# MCMC from Hamiltonian Dynamics

When  $i \neq j$ ,  $T(A_i|B_j) = T(B_j|A_i) = 0$  and detailed balance holds.

When  $i = j$ :

In the limit as regions  $A_k$  and  $B_k$  become smaller, the Hamiltonian  $H_X$  within each region  $X$  becomes effectively constant.  $\rightarrow$  The canonical probability density and the transition probabilities become effectively constant within each region.  $\rightarrow$  The detailed balance condition when  $i = j$  reads:

$$\frac{V}{Z} \exp(-H_{A_k}) \min[1, \exp(-H_{B_k} + H_{A_k})] =$$
$$\frac{V}{Z} \exp(-H_{B_k}) \min[1, \exp(-H_{A_k} + H_{B_k})]$$

This is seen to be true, so **detailed balance holds**.

# MCMC from Hamiltonian Dynamics

We know from the stuff before that **if the detailed balance holds, the Markov chain renders the distribution invariant.**

**So, the HMC algorithm leaves the canonical distribution invariant.**

## Ergodicity

Typically HMC is ergodic → **all states can be reached**, i.e. no traps. This may be compromised by periodic trajectories in the Leapfrog, when  $L\varepsilon \approx 2\pi$ .

# MCMC from Hamiltonian Dynamics

## Benefits of HMC

Consider sampling from a distribution for two variables that is bivariate Gaussian, with means of zero, and correlation 0.95. Regard these as “position” variables.

Introduce two corresponding “momentum” variables, defined to have a Gaussian distribution with means of zero, standard deviations of one, and zero correlation.

The Hamiltonian will then be

$$H(q, p) = q^T \Sigma^{-1} q / 2 + p^T p / 2, \text{ with covariance } \Sigma = \begin{bmatrix} 1 & 0.95 \\ 0.95 & 1 \end{bmatrix}.$$

(In multiple dimensions the inverse  $\Sigma^{-1}$  is computed by e.g. Gauss-Jordan.)

# MCMC from Hamiltonian Dynamics

Trajectories of a simulation based on this Hamiltonian.  $L = 25$ ,  $\varepsilon = 0.25$ . The initial state

$q$  moves from lower left to upper right corner and reverses – nothing like a random walk; efficient sampling.

This comes from the projection of  $p$  in diagonal direction changing slowly (gradient in this direction is small) → the direction of  $p$  stays the same for many leapfrog steps.

# MCMC from Hamiltonian Dynamics

Smaller-scale oscillations result from high correlation between the variables. These oscillations set an upper limit to the step size.

The value of the Hamiltonian (the rightmost figure) varies **only** because of numerical inaccuracy. If the trajectory was simulated correctly, it would stay constant. For this example, at a critical step size  $\varepsilon = 0.45$  the trajectory becomes unstable → the value of the Hamiltonian grows without bound

# MCMC from Hamiltonian Dynamics

**Note** that Neal (p. 16) gives the acceptance probability for the end point values of the Hamiltonian. This is the acceptance probability, if this difference due to numerical error is involved in the stage where new states are proposed.

But since the energy stays constant over the  $L$  steps, the proposals in HMC would be always accepted, if there were no numerical errors! This is not mentioned anywhere, but check if you can find something that would prove this not to be true.

The above then means that the only role that the Metropolis acceptance has in HMC is to reject proposals if the numerical errors get too large. Else, 100 % of the proposals are accepted, which, of course, means that HMC is extremely effective.

So, all the talk about Metropolis, but no mention about its redundancy! Another place for Bogey to step in...

# MCMC from Hamiltonian Dynamics

Comparing  $q$ 's of 2d random-walk and HMC. Correlation is 0.98.

RW of 20 iterations with 20 updates or leapfrog steps per iteration Metropolis and HMC of 20 leapfrog steps per trajectory.

Random-walk Metropolis

Hamiltonian Monte Carlo

# MCMC from Hamiltonian Dynamics

Two hundred iterations, starting with the 20 iterations shown above.

**Random-walk Metropolis**

**Hamiltonian Monte Carlo**

# MCMC from Hamiltonian Dynamics

Another way of visualising the motivation for/benefit of HMC. (Betancourt; also refer back to Lecture 5, p. 29.)

In high dimensions **the random-walk Metropolis** proposal density (green) is strongly biased towards the outside of the **typical set**. (a) Large proposal variances  $\rightarrow$  proposals will stray too far from the typical set and be rejected. (b) Smaller proposal variances  $\rightarrow$  proposals stay within the typical set and are accepted, but stay close to the initial point.

(a)

(b)

Both (a) and (b) result in slow exploration of the typical set.

# MCMC from Hamiltonian Dynamics

**HMC** incorporates coherent Markov transitions that remain within the typical set explore it faster than random-walk Metropolis.

# MCMC from Hamiltonian Dynamics

HMC, like RW Metropolis sampling, also involves a random-walk part. This comes in the momentum resampling. The variance of this part is given by the mass  $m_i$  in the kinetic energy; this gives  $\sigma^2$  in  $N(\mu, \sigma^2)$  for the auxiliary momentum variables  $p_i$ . And this should be chosen judiciously:

FIG 23. The momentum resampling in a Hamiltonian Markov transition randomly changes the energy, inducing a random walk between level sets. (a) When the energy transition distribution,  $\pi(E | q)$  is narrow relative to the marginal energy distribution,  $\pi(E)$ , this random walk will explore the marginal energy distribution only very slowly, requiring many expensive transitions to survey all of the relevant energies. (b) On the other hand, when the two distributions are well-matched the random walk will explore the marginal energy distribution extremely efficiently.

Btw: Other forms than  $K(p) = \sum_{i=1}^d \frac{p_i^2}{2m_i}$  for the kinetic energy have been tried with no success.

# MCMC from Hamiltonian Dynamics

*The benefit of HMC stated naively.*

RW MCMC: The variance in the position after  $n$  iterations of RW MCMC is proportional to  $n$ .  $\rightarrow$  The standard deviation of the amount moved (the distance) in  $q$ -space  $\propto \sqrt{n}$ .

HMC: The distance moved after  $n$  will tend to be proportional to  $n$ .

The advantage of HMC compared to movement by a random walk will be a factor roughly equal to the ratio of the standard deviations in the least confined direction and most confined direction.

There are ways to enhance HMC like using multiple step sizes.

**Note:** The following pseudocode is for **the first** iteration. In the following iterations you always start with  $q^*$  from the previous iteration, i.e.  $q_0 = q^*$  and then you update  $q^*$ .

# MCMC from Hamiltonian Dynamics

Pseudo algorithm for *a single iteration* of HMC in 1d ([R.M. Neal](#), p 14):

1. Initiate  $q$ .  $q^* = q_0$ .  $\leftarrow$  This is done only for the first iteration.
2. Sample  $p_0 \sim N(0,1)$
3. Make a half step for momentum  
 $p^* := p_0 - (\varepsilon/2) \cdot dU(q^*)/dq$
4. Alternate full steps for position and momentum  
for ( $i := 1, L$ )  
    Make a full step for the position  
     $q^* := q^* + \varepsilon \cdot p^*$   
    Make a full step for the momentum, except at the end  
    If  $i \neq L$ ,  $p^* := p^* - \varepsilon \cdot dU(q^*)/dq$
5. Make a half step for momentum at the end  
 $p^* := p^* - (\varepsilon/2) \cdot dU(q^*)/dq$
6. Negate momentum at the end of trajectory  
 $p^* := -p^*$
7. Evaluate potential and kinetic energies at start and end of trajectory  
 $U_0 = U(q_0); K_0 = p_0^2/2; U^* = U(q^*); K^* = (p^*)^2/2$
8. Accept or reject the proposed state  
 $q^* = q^*, \text{ if } u < \exp(U_0 - U^* + K_0 - K^*); q^* = q_0, \text{ if } u \geq \exp(U_0 - U^* + K_0 - K^*)$   
( $u \sim U(0,1)$ )

Note: This step inside the loop takes care of the 2 times half-steps.

THE FORM ON THE NEXT PAGE ENABLES CONSTRAINTS

# MCMC from Hamiltonian Dynamics

Pseudo algorithm for *a single iteration* of HMC in 1d ([R.M. Neal](#), p 14):

1. Initiate  $q$ .  $q^* = q_0$ .  $\leftarrow$  This is done only for the first iteration.
2. Sample  $p_0 \sim N(0,1)$ .  $p^* := p_0$

 $q^* = q^*, \text{ if } u < \exp(U_0 - U^* + K_0 - K^*); q^* = q_0, \text{ if } u \geq \exp(U_0 - U^* + K_0 - K^*)$   
( $u \sim U(0,1)$ )

Here you impose constraints  
(see the page after the next)

# MCMC from Hamiltonian Dynamics

Implementing constraints in HMC ([R.M. Neal](#), pp 36, 37)

Many distributions have a limited support, that is, the support  $\neq (-\infty, \infty)$ .

In such cases we need to impose constraints on  $q$ .

In order for the constraint to have minimal effect on the distribution it has to be imposed at every HMC step.

Imposing after  $L$  steps would lead to regions near the constraint (boundary) where the target distribution does not hold.

**In Hamiltonian dynamics constraints are elastic collisions** of the imaginary particle with boundaries: positions are “mirrored” with respect to boundaries.

# MCMC from Hamiltonian Dynamics

## Implementing constraints in HMC ([R.M. Neal](#), pp 36, 37)

For each variable,  $i = 1, \dots, d$ :

1) Let  $p'_i = p_i(t + \varepsilon/2)$

2) Let  $q'_i = q_i(t) + \varepsilon p'_i / m_i$

3) If  $q_i$  is constrained, repeat the following until  $q'_i$  satisfies all constraints:

a) If  $q_i$  has an upper constraint, and  $q'_i > u_i$

Let  $q'_i = u_i - (q'_i - u_i)$  and  $p'_i = -p'_i$

b) If  $q_i$  has a lower constraint, and  $q'_i < l_i$

Let  $q'_i = l_i + (l_i - q'_i)$  and  $p'_i = -p'_i$

4) Let  $q_i(t + \varepsilon) = q'_i$  and  $p_i(t + \varepsilon/2) = p'_i$

After this the momentum is propagated:  $p_i(t + \varepsilon) = p'_i - \frac{\varepsilon}{2} \frac{\partial U}{\partial q_i}(q(t + \varepsilon))$  (See next p.)

Figure 8: Modification to the leapfrog update of  $q$  (equation (2.29)) to handle constraints of the form  $q_i \leq u_i$  or  $q_i \geq l_i$ .

# Hamiltonian Dynamics

*The Leapfrog Method with Constraints*

$$p_i(t + \varepsilon/2) = p_i(t) - (\varepsilon/2) \frac{\partial U}{\partial q_i}(q(t))$$

$$q_i(t + \varepsilon) = q_i(t) + \varepsilon \frac{p_i(t + \varepsilon/2)}{m_i}$$

Upper constraint  $q_i(t + \varepsilon) \leq u_i$ :

If  $q_i(t + \varepsilon) > u_i$ :

$$q_i(t + \varepsilon) = u_i - (q_i(t + \varepsilon) - u_i), p_i(t + \varepsilon/2) = -p_i(t + \varepsilon/2)$$

Lower constraint  $q_i(t + \varepsilon) \geq l_i$ :

If  $q_i(t + \varepsilon) < l_i$ :

$$q_i(t + \varepsilon) = l_i + (l_i - q_i(t + \varepsilon)), p_i(t + \varepsilon/2) = -p_i(t + \varepsilon/2)$$

$$p_i(t + \varepsilon) = p_i(t + \varepsilon/2) - (\varepsilon/2) \frac{\partial U}{\partial q_i}(q(t + \varepsilon)) \quad .$$

# The Final View

Metropolis takes states towards the energy minimum, that is, towards maximum probability density.

$y = f(x)$  is  
proportional to  
the potential  
energy at  $x$

The motivation is not just to get there and stay there, but to sample significant regions (those around equilibria, typical set) for distributions.

- And then there's the dynamical (non-equilibrium) aspect, which is a different ball game altogether.

# CS-E5755 - Nonlinear Dynamics and Chaos, January – mid-April 2024

Something different if you should be curious...

Machine learning inference is increasingly being used with nonlinear dynamics.

# CS-E5755 Nonlinear Dynamics & Chaos

**Spring 2024 (the third and part of the Fourth period) 5 cr**

**Course book:** Steven Strogatz: Nonlinear Dynamics and Chaos

Nonlinear dynamics is relevant in the fields of population and social dynamics, mathematical biology, physics, electrical engineering, and many more. The course covers the fundamental concepts and tools for solving systems involving nonlinear dynamics and provides the basis for understanding chaotic dynamics.
